

Time Division Hashing

A New Scheduling Scheme for Wireless Ad-Hoc Networks

- Simulation Results
- Conclusions and Future Work

Outline

- Overview
- Proposed Algorithm
- Implementation
- Simulation Results
- Conclusions and Future Work

Overview

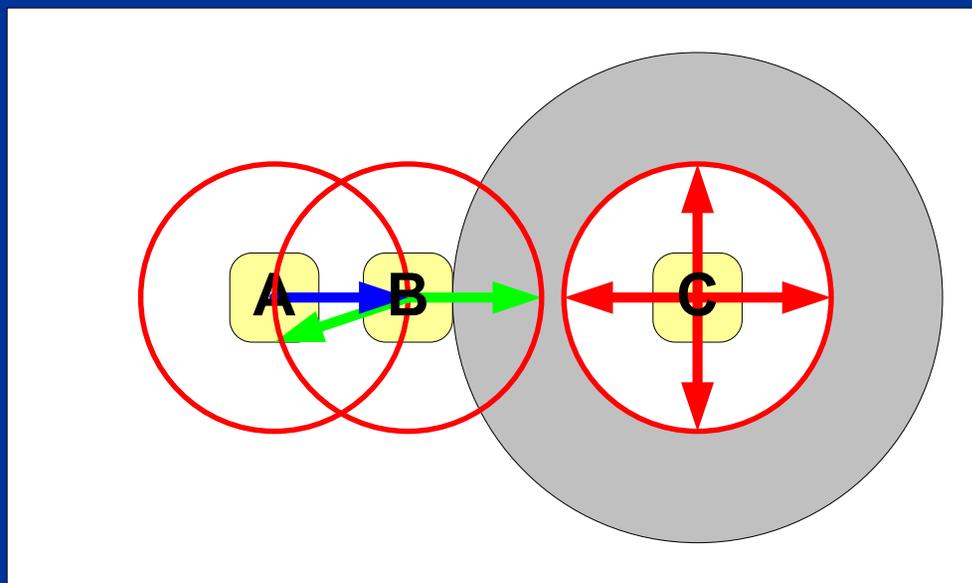

- Studied performance issues of current 802.11
- Proposed a new scheduling algorithm
 - TDH: Time Division Hashing
- Implemented TDH in NS-2
- Evaluated TDH in a variety of topologies

Background

- 802.11 – protocol for wireless communication
- RTS/CTS – Request To Send/Clear To Send
 - Handshake mechanism in 802.11 to gain access to the channel
 - Used to minimize packet collisions between neighboring nodes
- Exponential backoff used when collision is detected

Problems with Current Scheduling Scheme

- Low bit rate of RTS/CTS [spec802.11]
 - ~5-10 times lower than the data rate
- Ineffectiveness of detecting hidden nodes in interference range [KXu03]

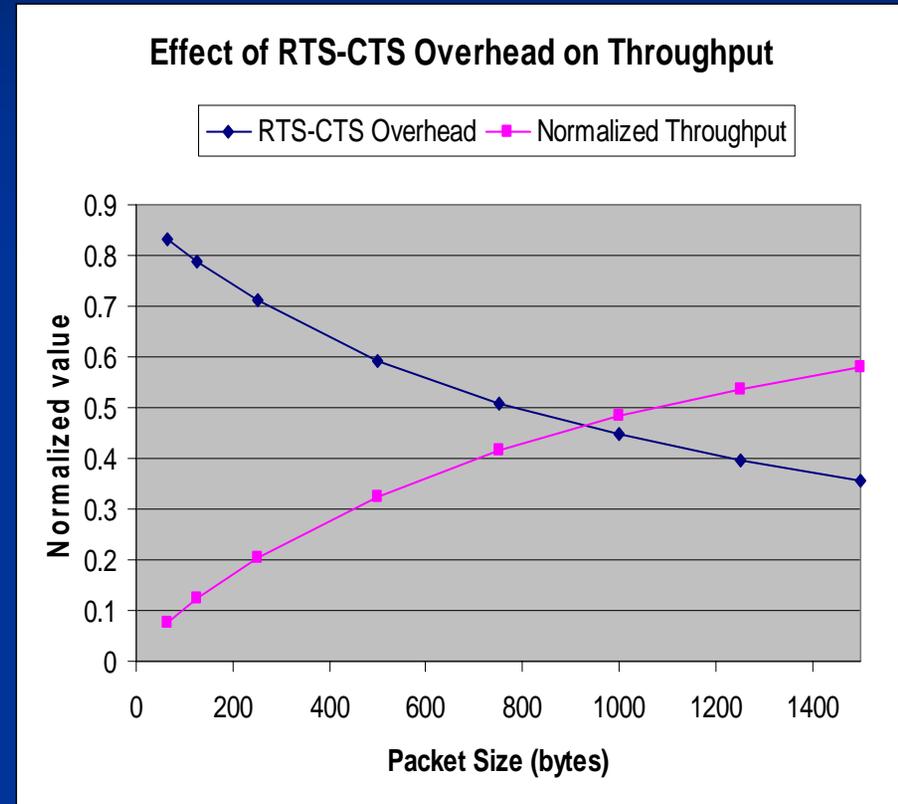

Problems with Current Scheduling Scheme

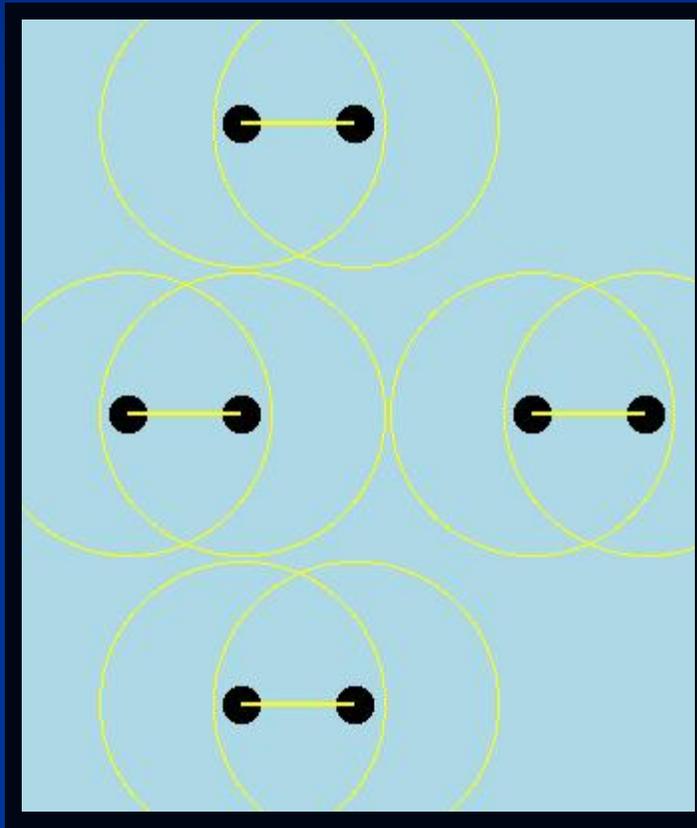

- Performance degradation due to exposed terminal problems [SXu02]
- Aggressive (Exponential) backoff causes long idle time [Li01]
- Unfairness with transmitter-based contention [Bharghavan94]

RTS/CTS Overhead

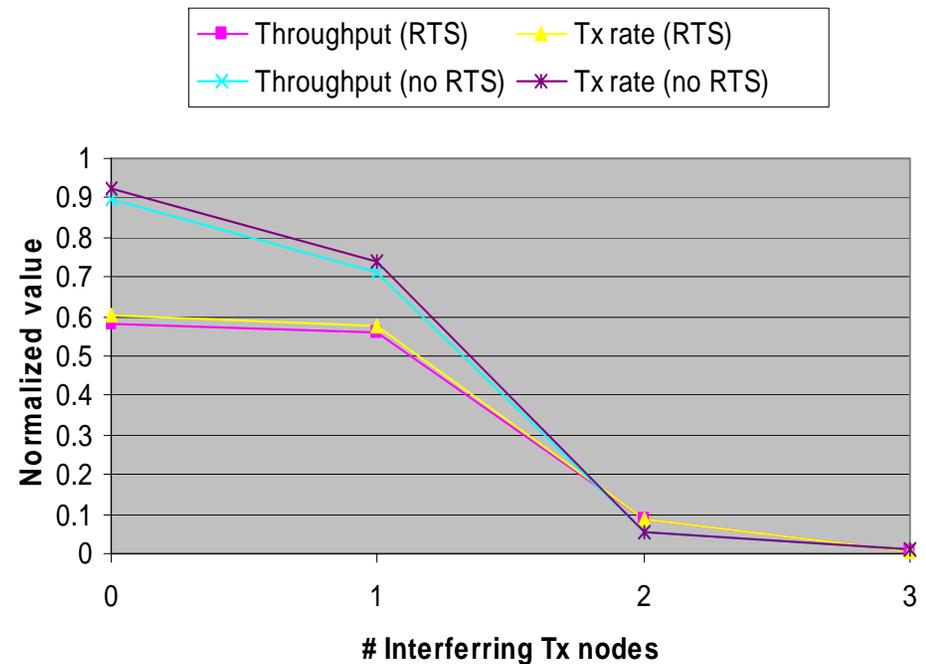

- 11Mbps Channel Bit Rate, 1Mbps RTS/CTS Transmission Rate
- Due to RTS/CTS overhead, throughput is at max 58% for 1500-byte packets

Interference Problem

Ineffectiveness of RTS-CTS due to Interference

Outline

- Overview
- Proposed Algorithm
- Implementation
- Simulation Results
- Conclusions and Future Work

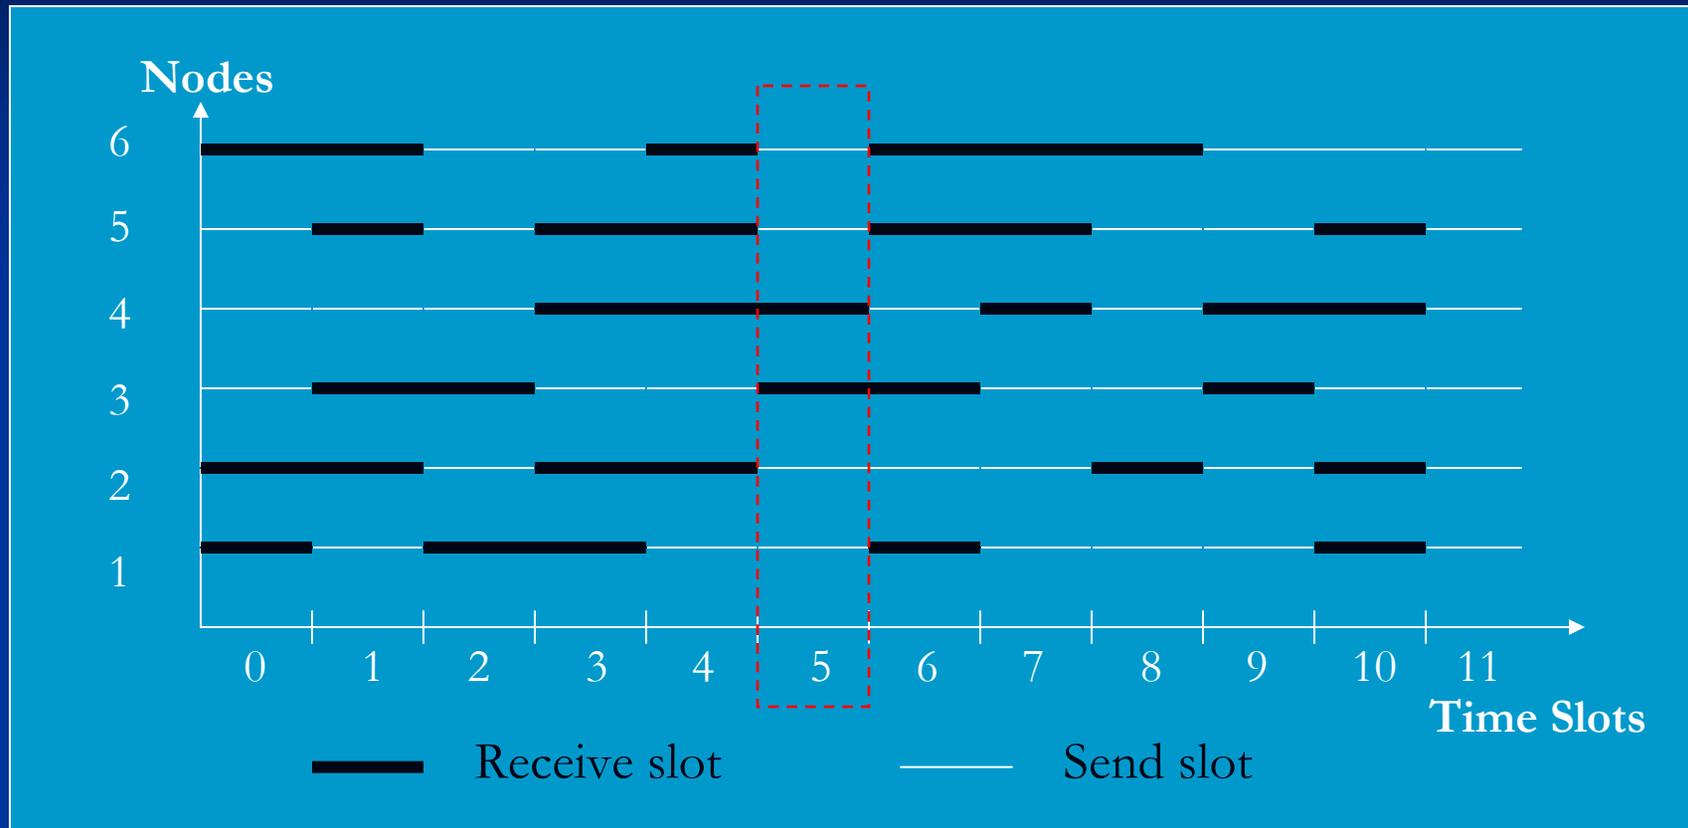

Proposed Scheme: TDH

- Based on Tim Shepard's clock exchange scheduling algorithm for Packet Radio Networks [Shepard95]
- Fixed-sized time slot and deterministic sending/receiving schedule
- Eliminate the overhead from RTS/CTS and long channel idle time due to aggressive backoffs

Time Division Hashing

- Time is *divided* into fixed-sized slots
- Each node has a unique seed value that is known to all other nodes
- Status (sending/receiving) of a node for a specific time slot is decided deterministically by hashing
- Parameters of the algorithm
 - p : probability that the node is in 'send' mode
 - n : number of slots per second
 - s : random seed value of a node

Deterministic Send/Receive Schedule

Node 2 can send a package to 3 in time slot 5 if they are neighboring.

TDH Algorithm

- Initialize seed s to random value
- **PrevTimes**: table containing the time for which the last packet was scheduled for each neighbor
- **ScheduledTimes**: list of all the time slots for which packets have already been scheduled
- **SchedulePacket** ($recvID$, $currentTime$)
 - t = beginning of next time slot from $currentTime$
 - if ($PrevTimes(recvID) > t$)
then $t = PrevTimes(recvID) + slotLength$
 - $s_{recv} =$ seed of receiver

How TDH Works

- loop
 - increment t till a slot is found that is not in **ScheduledTimes**
 - $\text{senderMode} = \text{hash}(s + t)$
 - $\text{destMode} = \text{hash}(s_{\text{recv}} + t)$
 - if ($\text{senderMode} \leq p$ and $\text{destMode} > p$)
 - Schedule packet for t
 - Update **ScheduledTimes** and **PrevTimes**
 - return t
 - else
 - $t = t + \text{slotLength}$

Features of TDH

- Unlike [Shepard95], TDH requires no explicit seed exchange between neighbors (the unique MAC address ID can be used as the random seed)
- The parameter p (send probability) can be tuned to achieve the best performance for a particular topology
- The packet and the ACK are exchanged in the same time slot
- The size of a time slot is dependent on the packet size
$$\text{slotLength} = \text{time to transmit packet} + \text{time to transmit ACK} \\ + 2 * (\text{time to switch radio})$$
- If no packet is scheduled to be sent during a send time slot, receiver is automatically turned on to listen to the traffic

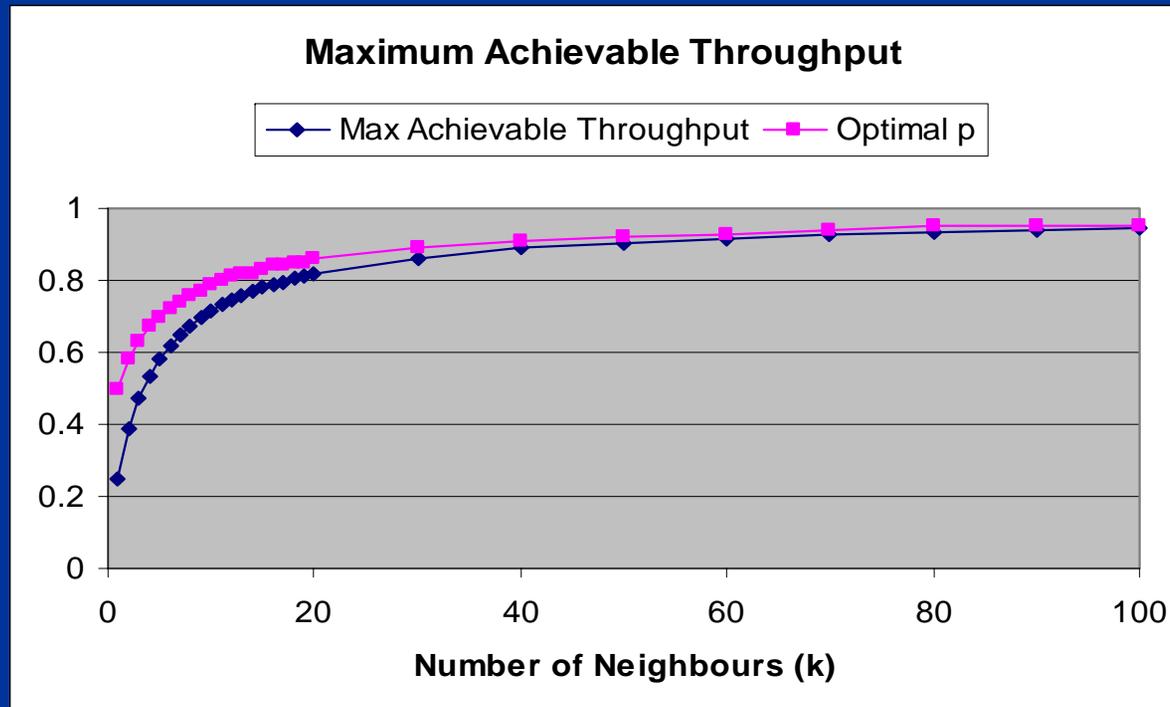

Theoretical Throughput

p = Probability of a node sending, k = Number of neighbor

Max Throughput

= (Prob of the sender in Tx) * (Prob of at least one neighbor in Rx)

$$= p (1 - p^k) = p - p^{k+1}$$

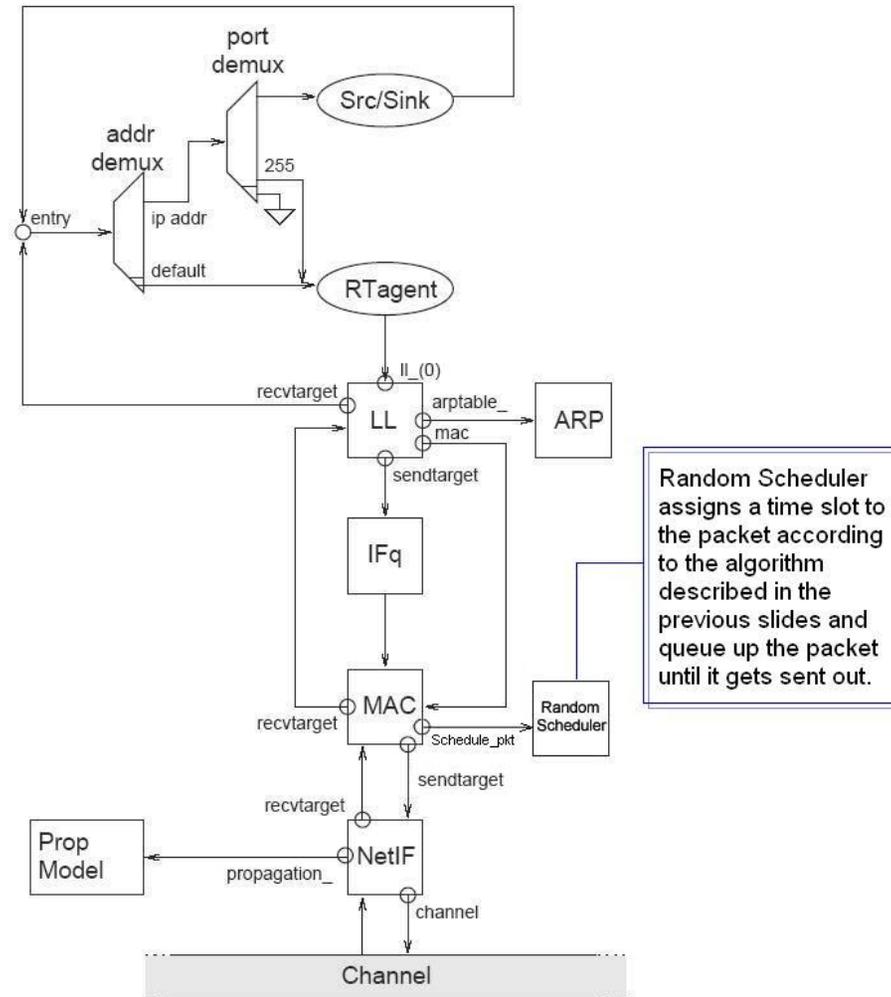

Outline

- Overview
- Proposed Algorithm
- Implementation
- Simulation Results
- Conclusions and Future Work

Implementation Strategy

- **Code Base:** The CMU Monarch Project's Wireless and Mobility Extensions to *ns*.
- **Our Extension:** Complete rewrite of MAC layer protocol
 - Remove exchange of RTS / CTS
 - Eliminate backoffs and use of Network Allocation Vector
 - Implement and employ TDH scheduling algorithm

Schematics of a Mobile Node

Issues Encountered

- Support for multiple outstanding packets in the MAC layer
- Management of state for the scheduled packets
- Flow control with the link layer
- Prevention of packet reordering

Outline

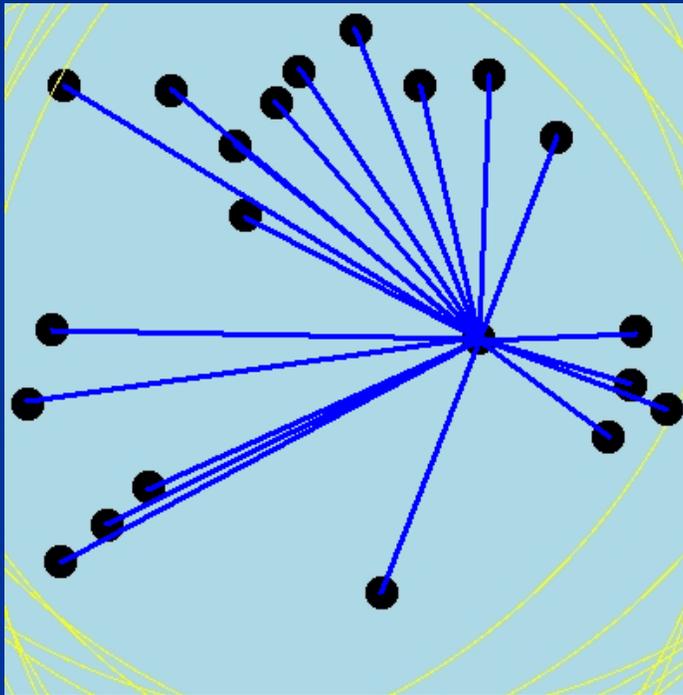

- Overview
- Proposed Algorithm
- Implementation
- Simulation Results
- Conclusions and Future Work

Simulation Results

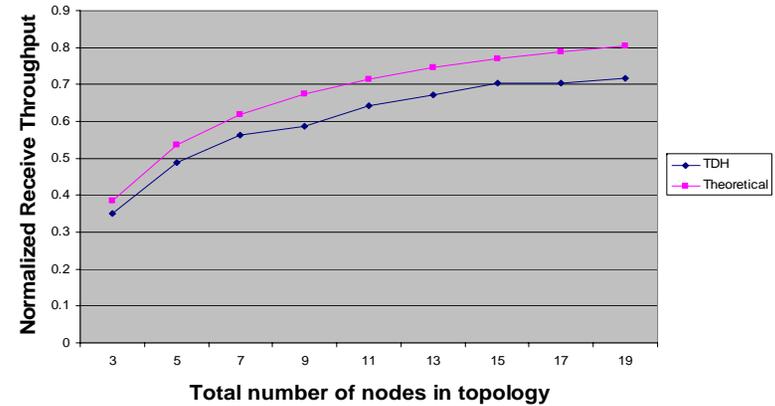

■ Topologies studied:

- Single sender
- Access Point
- Clique
- Chain
- Random

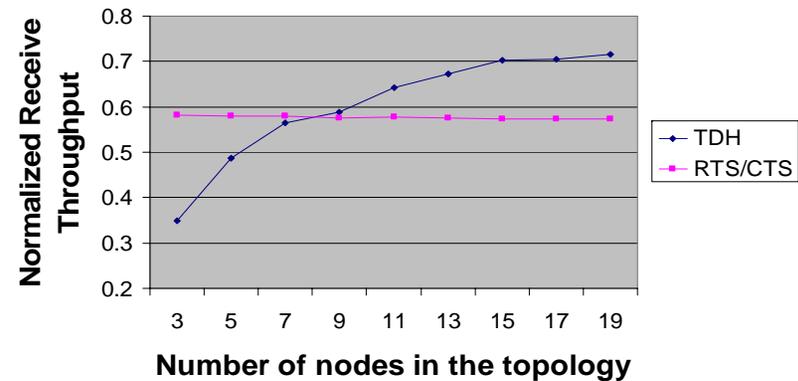

Single Sender Topology

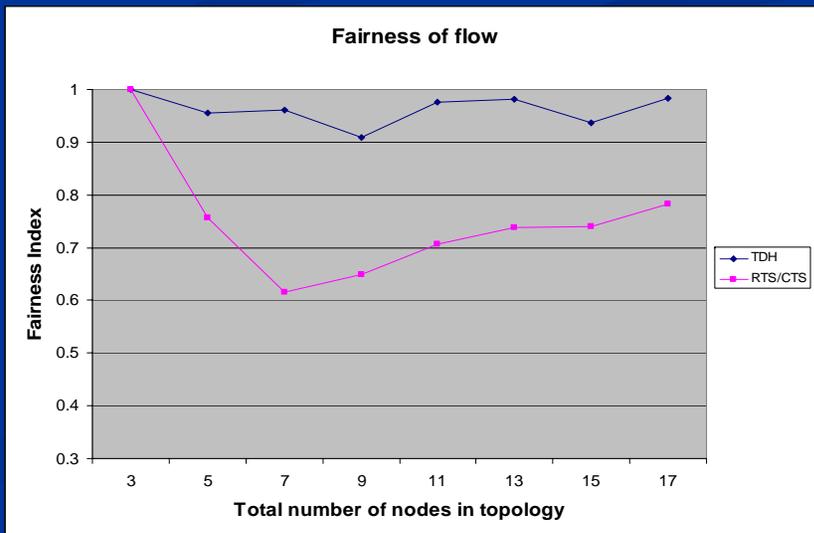

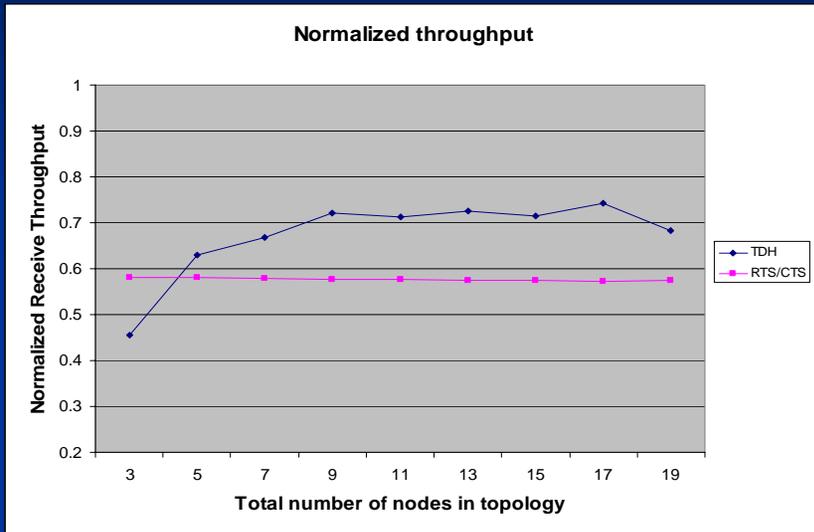

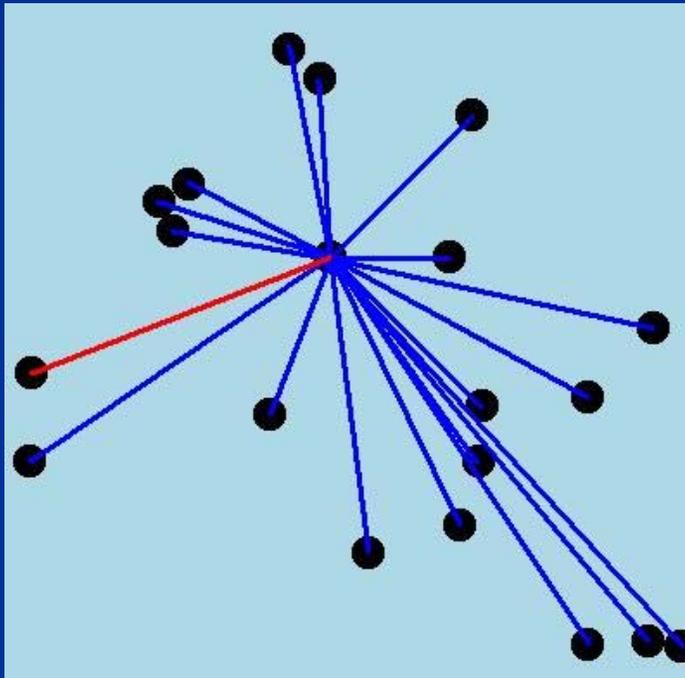

Normalized Throughput for single sender
(theoretical vs. actual)

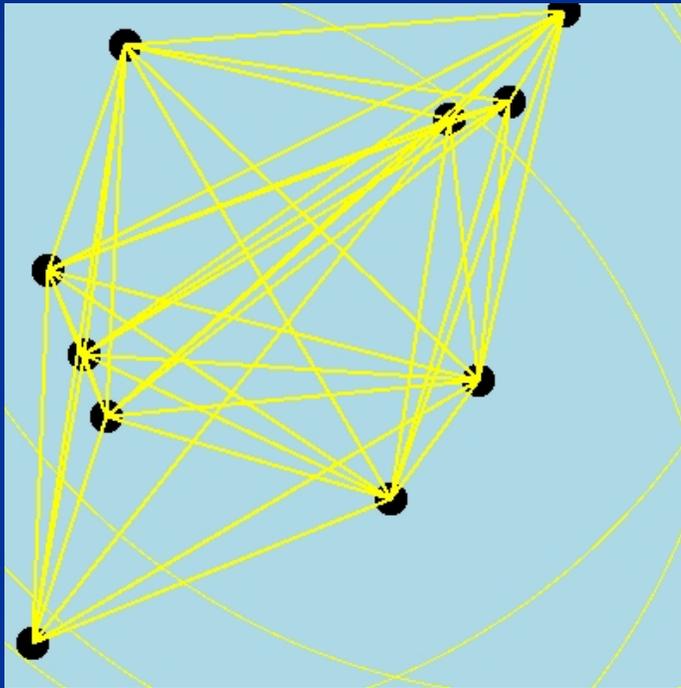

Normalized Throughput
(packet size = 1500 bytes)

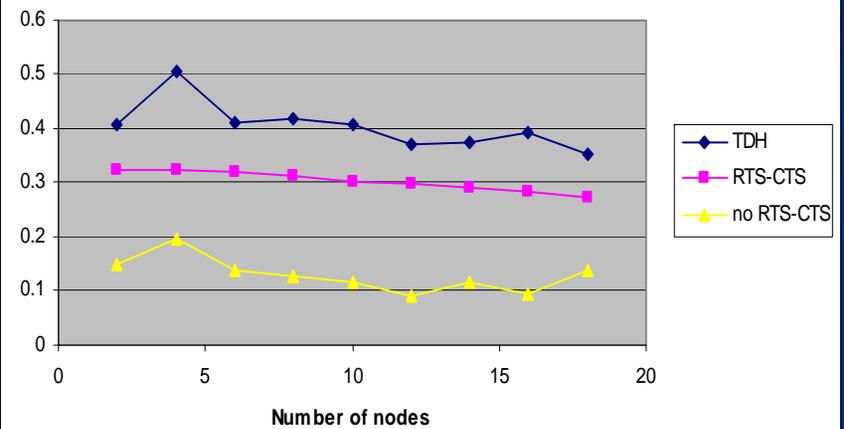

Access Point Topology

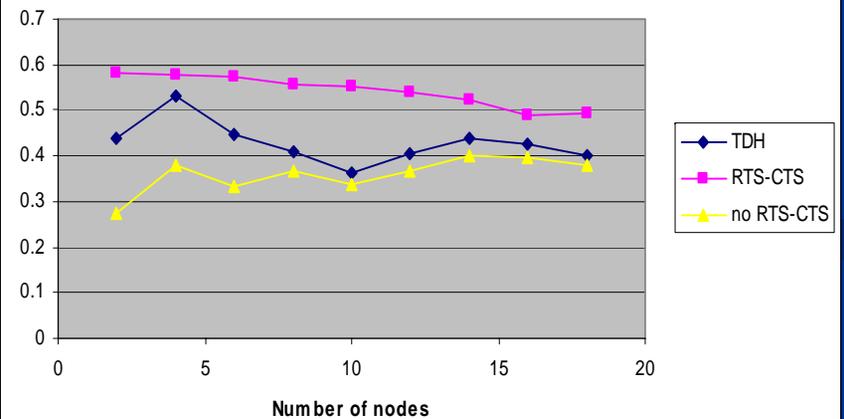

Clique Topology

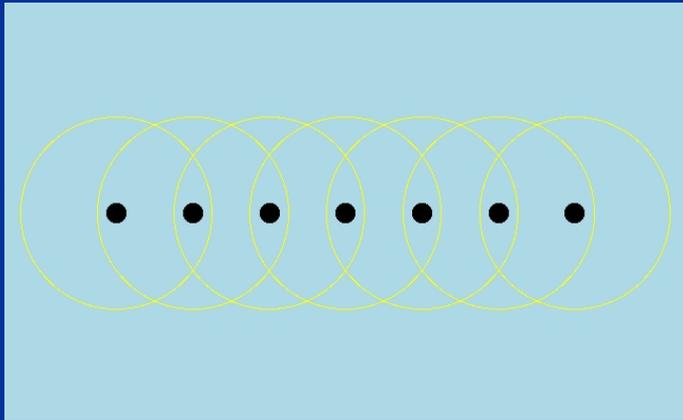

Normalized Throughput (500-byte)

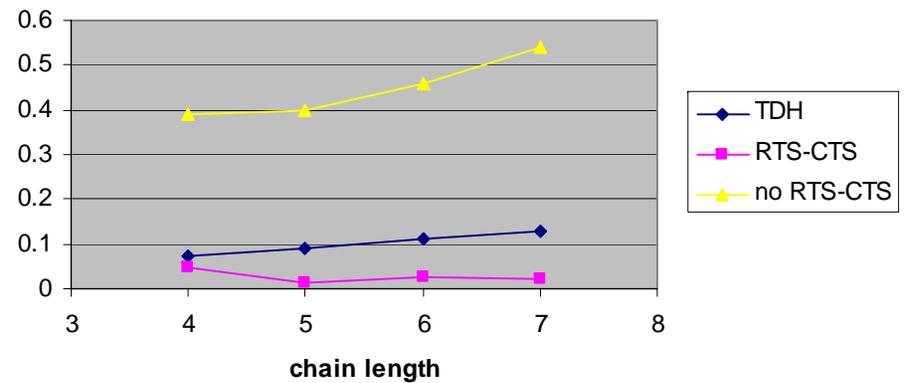

Normalized Throughput (1500-byte)

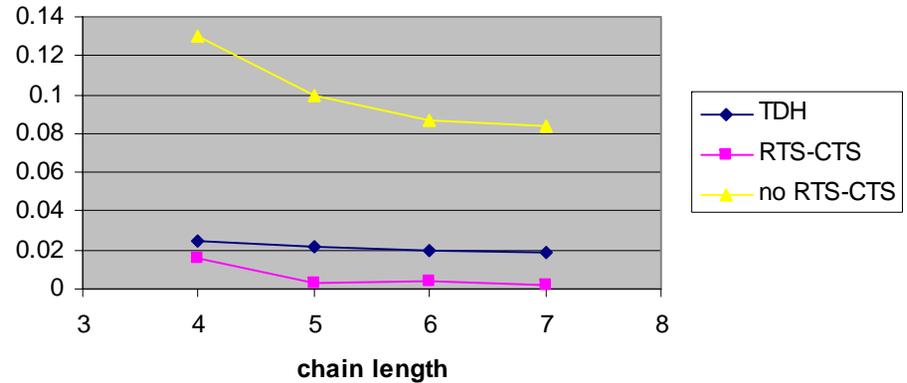

Chain Topology

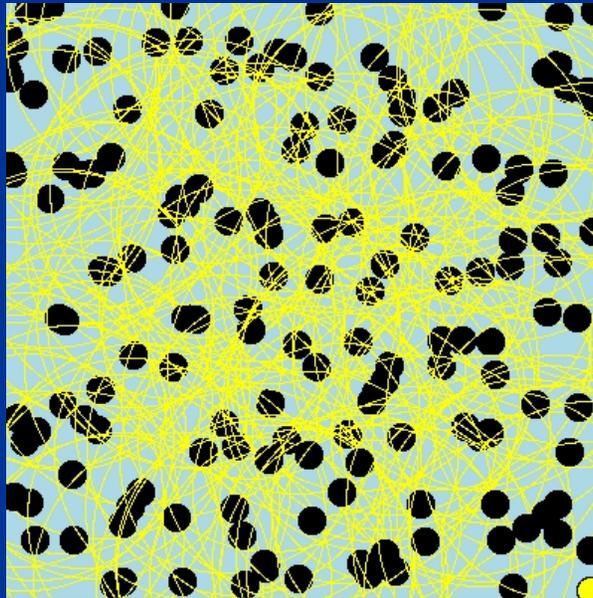

Normalized Aggregate Throughput

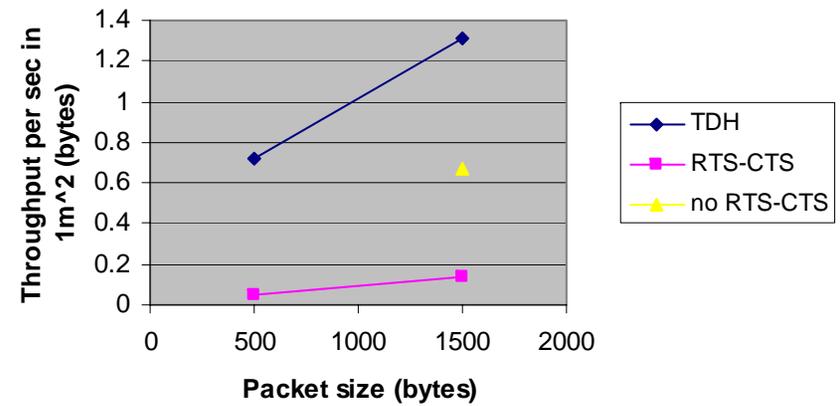

Normalized Forwarding Rate

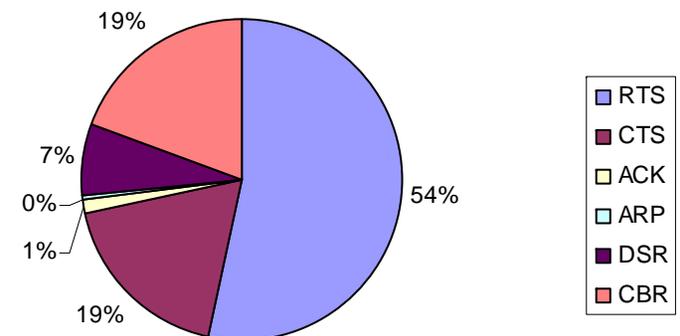

Random Topology

Throughput of Random Topology

Transmission Time for Random Topology

Summary of Results

Normalized Throughput Improvement with TDH

Scenario	TDH	802.11	Improvement
Single Sender	0.716	0.573	125 %
Access Point	0.742	0.572	130 %
Clique	0.507	0.325	156 %
Chain	0.128	0.020	640 %
Random*	1.310	0.138	949 %

* Throughput per m²

Outline

- Overview
- Proposed Algorithm
- Implementation
- Simulation Results
- Conclusions and Future Work

What We Gained from TDH

- 802.11 performance was significantly degraded by its backoff mechanism and RTS-CTS resulted in more harm than good for congested networks
- TDH is a simple scheme that avoids some of these problems and gives better performance
- TDH treats each Tx-Rx independently, resulting in better fairness

Some Weaknesses of TDH

- High drop rates due to collisions
- Performance degradation in very sparse networks
- Assumption of static p and fixed slot size

Future Work

- Analysis of impact of collisions on transport layer
- Better slot management using subslots
- Dynamic adjustment of p
- Investigate with higher bit rates like 54Mbps
